Optical properties of pulse electrodeposited ZnS films

K. R. Murali

ECMS Division, CSIR-CECRI, Karaikudi, India

Abstract: ZnS films were deposited by the pulse plating technique at different duty cycles in the range of 6 – 50 % and at a constant current density of 10 mA cm\(^{-2}\). The films exhibited single phase hexagonal ZnS. The grain size increased with decrease of duty cycle. Optical band gap of the films increased from 3.83 – 4.01 eV with increase of duty cycle. Optical constants (refractive index, n, extinction co-efficient, k, dielectric constant) of the films were obtained in the wavelength range 300-1850 nm by using spectrophotometric measurement. The obtained results concerning the absorption index yield the energy gap in addition to the type of the allowed optical transitions. N/m* ratio has been obtained from refractive index data. The dispersion of refractive index is analyzed by using a single oscillator model.

Keywords: electrodeposition, electronic materials, optical properties, semiconductors, thin films

I. Introduction

Zinc sulfide (ZnS) is found in nature as zinc-blende (also called sphalerite or \(\beta\)-ZnS and with a cubic structure) and wurtzite (\(\alpha\)-ZnS, which is a hexagonal structure). The names of these minerals are used to designate the corresponding crystal structures. It is a II–VI compound semiconductor material and is commercially used in solar cells [3], infrared windows [4], and phosphor materials by doping with transition or rare-earth metals [5,6]. There has been growing interest in developing techniques to prepare semiconductor ZnS thin films. ZnS thin films are produced using various techniques, including radio frequency (RF) magnetron sputtering [7], chemical vapor deposition (CVD) [8], solvothermal [9] and chemical bath deposition [10]. In an earlier paper, details of pulse plating technique at different duty cycles in the range of 20 – 60 % and the structural, morphological and band gap of the films were reported [11]. In this work, we report on the deposition of ZnS thin films at different duty cycles in the range of 6 – 50 %, using pulse electrodeposition technique. Optical properties of the films are analyzed and the optical constants were evaluated and discussed.

In pulse electrodeposition [12,13] the potential or current is alternated swiftly between two different values. This results in a series of pulses of equal amplitude, duration and polarity, separated by zero current. Each pulse consists of an ON-time (\(T_{ON}\)) during which potential and/current is applied, and an OFF-time (\(T_{OFF}\)) during which zero current is applied. It is possible to control the deposited film composition and thickness in an atomic order by regulating the pulse amplitude and width. They favor the initiation of grain nuclei and greatly increase the number of grains per unit area resulting in finer grained deposit with better properties than conventionally plated coatings. The sum of the ON and OFF times constitute one pulse cycle. The duty cycle is defined as follows:

\[\text{Duty Cycle} (\%) = \frac{(\text{ON time})}{(\text{ON time} + \text{OFF time})} \times 100 \quad (1)\]

A duty cycle of 100% corresponds to conventional plating because OFF time is zero. In practice, pulse plating usually involves a duty cycle of 5% or greater. During the ON time, the concentration of the metal ions to be deposited is reduced within a certain distance from the cathode surface. This so-called diffusion layer pulsates with the same frequency as the applied pulse current. Its thickness is also related to \(i_p\), but reaches a limiting value governed primarily by the diffusion coefficient of the metal ions. During the OFF time the concentration of the metal ions build up again by diffusion from the bulk electrolyte and will reach the equilibrium concentration of the bulk electrolyte if enough time is allowed. These variables result in two important characteristic features of pulse plating which make it useful for alloy plating as well as property changes as mentioned earlier.

Pulse plating technique has distinct advantages compared to conventional electrodeposition namely, crack free, hard deposits and fine grained films with more uniformity, lower porosity and better adhesion. It is well known that by using pulse current for electrodeposition of metals and alloys it is possible to exercise greater control over the properties of electrodeposits and to improve them by modifying their microstructures [14]. It has been reported that a significant reduction in internal stress could be obtained when pulse current was used, compared to the use of conventional direct current [15].

II. Materials And Methods

ZnS films were pulse electrodeposited at 10 mA cm\(^{-2}\) at room temperature and at different duty cycles in the range of 6 – 50 %. Tin oxide coated glass substrates were used. The total deposition time was kept...
constant at 30 min. Thickness of the films measured by Mitutoyo surface profilometer was in the range of 525 nm – 1450 nm with decrease of duty cycle. The films were characterized by Xpertpanalytical x-ray diffraction unit with CuKα radiation. Optical measurements were recorded using an Hitachi UV–Vis-IR spectro-photometer. Composition of the films was estimated by EDS attachment to JOEL SEM.

III. Results And Discussion

Fig. 1 shows a typical XRD pattern of the ZnS film grown by pulse electrodeposition at different duty cycles. The diffraction pattern of the films revealed a polycrystalline wurtzite crystal structure and the presence of two phases corresponding to ZnS (JCPDS no. 36-1450) [16] with a strong preferred orientation along the hexagonal (110) ZnS plane direction. Other characteristic planes for hexagonal ZnS were observed as weak peaks at (100), (002), (101), (110), (103), (112) and (203). The evaluated lattice parameters were \( a = 3.76 \) Å and \( c = 24.92 \) Å. The crystallite size was calculated from the Full width half maximum of the diffraction profiles using Scherrer’s equation

\[
D = \frac{0.95 \lambda}{\beta\cos\theta} \quad \text{(2)}
\]

where, \( D \) is the crystallite size, \( \lambda \) is the wavelength of CuKα radiation, \( \beta \) is the full width at half maximum, \( \theta \) is the Bragg angle. The crystallite size decreased from 80 nm – 40 nm with increase of duty cycle. The crystallite size and thickness of the films are shown in Table.1. The trend of decreasing grain size with increasing current on-time can best be explained by an increased number of nucleation sites caused by the higher overpotential at longer current on-times. The same behavior of increasing overpotential with current on-time was also found during zinc deposition from a chloride-based electrolyte [17]. Moreover, at low duty cycles, the OFF time is more compared to ON time, hence, the deposited species have sufficient time to nucleate and grow thus increasing the thickness. As the duty cycle increases, the ON time increases and OFF time decreases, which was found to yield grain growth, which can be explained by both the decrease of overpotential and longer time for the adatoms to surface migrate and enhance the crystal grain-growth process, resulting in a decreased rate of nucleation and growth rate, hence, the thickness of the films decreases.

Table 1: Variation of crystallite size and thickness with duty cycle for ZnS films deposited at different duty cycles

Composition of the films was determined by the Energy dispersive x-ray analysis (EDAX) attachment of the Scanning Electron Microscope (SEM). At low duty cycles, more concentration of S is deposited due to the fact that S is more noble compared to Zn. As the duty cycle is increased, due to increase of ON time, more Zn is deposited along with S, hence the percentage of Zn increases. Fig.2 shows the Energy dispersive spectrum (EDS) spectrum of ZnS films deposited at 50 % duty cycle. Table 2 shows the composition of the films deposited at different duty cycles.

Fig. 3 shows the transmission spectra of the ZnS films deposited at different duty cycles. The spectra exhibit interference fringes and the value of the refractive index was estimated by the envelope method [18] as follows:

\[ n = \sqrt{N + (N^2 - n_s^2)} \]  
\[ N = \frac{(n_s^2 + 1)/2 + 2 n_s (T_{max} - T_{min})}{T_{max} T_{min}} \]  

where \( n_s \) is the refractive index of the substrate, \( T_{max} \) and \( T_{min} \) are the maximum and minimum transmittances at the same wavelength in the fitted envelope curve on a transmittance spectrum. The value of the refractive index at 450 nm, calculated from the above equations was in the range of 4.30 - 4.00 for the samples deposited at different duty cycle. This value is comparable to the values obtained on chemical bath deposited ZnS films [19]. Variation of refractive index with wavelength is shown in Fig. 4.

The value of the absorption co-efficient (\( \alpha \)) was calculated using the relation

\[ \alpha = \frac{1}{\lambda} \ln \left\{ \frac{(n-1)(n-n_s)(n+1)(n-n_s)}{(n-1)(n-n_s)(n+1)(n-n_s) \left[ (T_{max}/T_{min})^2 + 1 \right]} \right\} \]  

where \( d \) is the thickness of the film and the other parameters have the usual meaning as given for equation (4). The films exhibited a high absorption co-efficient of the order of \( 10^4 \text{ cm}^{-1} \). A plot of \( (\alpha \lambda)^2 \) against \( h\nu \) as indicated in Fig. 5, exhibits linear behavior near the band edge, the band gap of the deposited films was determined to be in the range of 3.83 - 4.01 eV. The band gap slightly increased with increase of duty cycle, due to the decrease of grain size. The band gap of ZnS thin film prepared by chemical bath deposition technique was in the range of 3.70 eV - 4.01 eV [19]. Extinction coefficient was determined from the absorption coefficient using the following relation. Fig. 6 shows the variation of extinction coefficient with wavelength.

\[ k = \alpha \lambda / 4\pi \]  

where \( \alpha \) is the absorption coefficient and \( \lambda \) is the wavelength. As seen from the figure, the extinction coefficient decreases with the increase in the wavelength. The decrease in extinction coefficient with increase in wavelength shows that the fraction of light lost due to absorbance decreases.
In transparent region, the relation between the optical dielectric constant, $\varepsilon_1$, the wavelength, $\lambda$, and the refractive index, $n$, is given by the following equation [20]:

$$\varepsilon_1 = n^2 = \varepsilon_L - D \lambda^2 \quad \text{................(7)}$$

where $\varepsilon_1$ is the real part of the dielectric constant, $\varepsilon_L$ is the lattice dielectric constant or (the high-frequency dielectric constant) and $D$ is a constant depending on the ratio of carrier concentration to the effective mass:

$$D = (e^2 N) / (4\pi^2 \varepsilon_0 m^* c^2) \quad \text{..................(8)}$$

where 'e' is the charge of the electron, $N$ is the free charge carrier concentration, $\varepsilon_0$ is the permittivity of free space, $m^*$ is the effective mass of the electron and $c$ is the velocity of light [21]. Fig. 7. shows the relation between $n^2$ and $\lambda^2$ for the ZnS thin films deposited at different duty cycles. It is observed that the dependence $\varepsilon_1 (= n^2)$, on $\lambda^2$ is linear at longer wavelengths. Extrapolating the linear part of this dependence to zero wavelength gives the value of $\varepsilon_L$ and from the slope of this linear part, the constant $D$ can be obtained, from which the value ($N/m^*$) for the thin films can be obtained (Table-3).
According to the single-effective oscillator model proposed by Wemple and DiDomenico [22], the optical data can be described by an excellent approximation using the relation

$$n^2 - 1 = \frac{E_0 E_d}{E_0^2 - E^2}$$  \hspace{1cm} (9)$$

where $E = h\nu$ is the photon energy, $n$ is the refractive index, $E_0$ is the single-effective oscillator energy and $E_d$ is the dispersion energy which is a measure of the average strength of the interband optical transitions. Plotting $(n^2 - 1)^{1/2}$ against $E^2$ gives the oscillator parameters by fitting a straight line. Figure 8 shows the plot of $(n^2 - 1)^{1/2}$ vs $E^2$ for the films deposited at different duty cycles. The values of $E_0$ and $E_d$ can then be calculated from the slope $(E_0 E_d)^{1/2}$ and the intercept on the vertical axis $(E_0/E_d)$. The values of the static refractive index ($n_0$) can be calculated by extrapolating the Wemple–DiDomenico dispersion equation (8) to $E \to 0$. The calculated values of $n_0$ are 3.0, 3.8, 4.2 and 4.3, for the films deposited at different duty cycle. The calculated values of $n_0$, $E_0$ and $E_d$ are listed in Table 3. In addition, the optical band gap ($E_g$) determined from the Wemple–DiDomenico dispersion parameter $E_0$ using the relation $E_g = E_0/2$, are also in good agreement with the band gap values determined from the $(\alpha h\nu)^2$ vs $h\nu$ plot of Fig.5.
M₁ and M₃ Moments of the Optical Spectra for the ZnS thin films were obtained from the following relations [23].

\[
E_0^2 = M_1 / M_3 \quad \text{………………(10)}
\]

The single-oscillator parameters E₀ and E₃ are related to the imaginary component εᵢ of the complex dielectric constant. Thus, determining the moments is very important for developing optical applications of the optical material. The obtained values are given in Table 3. The obtained M₁ and M₃ moments increased with duty cycle.

### IV. Conclusions

In this study, the effect of annealing on the structural, optical, and electrical properties of amorphous ZnS thin films deposited by a chemical bath deposition method has been investigated. X-ray diffraction analysis indicated that as-deposited ZnS films were amorphous, and heat treatments improved slightly the amorphous structure. The Raman spectra of annealed ZnS samples showed first-, second-, and third-order Raman phonons and their compositions. Also, all the films have a direct bandgap, and it decreased from 4.01 to 3.74eV with an increase in annealing temperature. These values are in good agreement with the literature.
