Abstract: About 0.5% of Indian population is affected by oral submucous fibrosis (OSMF) and it has generated considerable interest in medical science field because it is posing a major health problem. Along with OSMF, oral squamous cell carcinoma (OSCC) comprises a bulk of all oral malignancies, and it has been proven by studying that OSMF has 7-13% malignant potential. Hence, the study was carried out to study collagen fiber histopathologically for the orientation and thickness of collagen fibers in OSMF, OSCC and OSCC with OSMF with picrosirius red staining and was examined with polarizing microscope.

Material & method: Each fifteen cases of histologically diagnosed, OSMF, OSCC and OSCC with OSMF were taken for the study and five specimen of normal buccal mucosa were also incorporated as a control group. All were stained with haematoxylin, eosin and picrosirius red staining for evaluation under polarised microscope.

Result: In the study, we found there is a gradual change in birefringence of collagen fibers from red to orange to yellowish green as from OSMF to OSCM with OSCC and to OSCC.

Conclusion: The present study indicated that the change in orientation and thickness of collagen fibers in OSMF could act as a prognostic marker indicative of malignant transformation.

Keywords: Malignancies, Picro Sirius red, polarized microscope

I. Introduction

OSMF is not only a well-recognized malignant condition of oral cavity illustrated by inflammation as well as progressive fibrosis of lamina propria and deeper connective tissue but also most frequently encounter premalignancy and a never ending illness with dangerous onset, affecting the pharynx and upper digestive system as well. In 1952, OSMF was acknowledge condition as “Atrophia idiopathica (tropica) mucosae oris” in five Indian women in Kenya. About 0.5% of Indian population is affected by OSMF. Since then, the disease has generated huge interest in the field of medical science. Epithelial precancerous development that leads to well documented molecular and structural changes in the epithelium. Recently, it has been recognized that stromal biology is also altered significantly with preinvasive disease. OSCC comprises a bulk of all oral malignancies and it has been proven by studied that OSMF has 7-13% malignant potential.

In OSCC, cell invade the stroma in the form of islands, strands or sheets, which are embedded or surrounded by an extracellular matrix, thus producing reactive changes in the stroma. There is also concentrate deposition of collagen fibers in the connective tissue stroma due to decrease in its degradation by various inhibitory mechanisms. The synthesis of collagen is mediated by various growth factors, hormones, cytokines, lymphokines and TNF-β. This collagen in extracellular matrix having important role in maintaining structural integrity and tissue functions of the body and is consider as a barrier for the spread of the tumor also. The proteolytic remodeling of extracellular matrix leads to abundant changes in the collagenous stroma, helps in tumor invasion and progression.

As collagen is a basic amino acid and has a strong affinity for acidic dyes. Sirius red is an elongated dye molecule responds with the collagen and increases the birefringence property of collagen. Many methods to detect, quantify and evaluate the nature of collagen are available, in a few studies, it was found they were using

the picrosirius red stain as it has capability to detect thin collagen fibers which are not possible with routine staining procedure and helps to differentiate between mature and immature collagen fibers. 

In this study, collagen was studied histopathologically for the orientation and thickness of collagen fibres in OSMF, OSCC and OSCC with OSMF with picrosirius red staining and examined with polarising microscope. The present study helps in documentation of connective tissue changes in OSMF, OSCC and OSCC with OSMF. The objectives set was to study the orientation and thickness of collagen fibres in OSMF, OSCC and OSCC with OSMF.

II. Material & Method

Fifteen paraffin embedded blocks of histopathologically diagnosed cases each of OSMF, OSCC and OSCC with OSMF were obtained from the archives of the department of Oral Pathology and Microbiology and 5 cases of normal buccal mucosa were included in the study. The OSCC & OSMF & OSMF with OSCC sections were stained subsequently with picrosirius red (Sirius red in a saturated picric acid solution,7,8 which were evaluated under polarising microscope. Only Stage III OSMF (moderately advanced) were considered in this study grading for which done according to Pinbrg et.al histopathological grading system for OSMF.5 For OSCC, grading was done according to Brynes histological malignancy grading system,9 and moderately differentiated OSCC cases were considered and cases of OSMF which were transformed to OSCC were included in the study.

The sections were observed under polarizing microscope. A total of 10 high power field from each section are visualized and their color was noted for interpretation and comparison of collagen fiber hue as show in table.1.

III. Results

The study included total 50 cases in which 5 were the control group, which shows haphazardly arranged collagen fibers in the connective tissue stroma with respect to epithelium. Ten cases of OSMF showing predominantly thick collagen fibers which are having orange red to reddish birefringence. (Figure 1) The reason for this finding is the collagen fibers in OSMF is hyalinized and tightly packed, also the less number of thin fibers giving rise to red colour through out the section. And 12 cases shows the collagen fibers in OSMF were oriented parallel to the epithelium(Figure 2).

In OSCC, 10 cases were showing predominantly greenish yellow birefringence (Figure 4). The reason for this is thought to be the decrease in thick fibers and more accumulation of thin fibers giving greenish yellow color to the section. Also 13 cases showing the collagen fibers are arranged haphazardly in relation with epithelium (Figure 3).

In OSMF with OSCC we observed 8 cases giving predominantly greenish yellow birefringence and 4 case showing yellow orange birefringence (Figure 5) and 4 cases giving a mixed picture of these two birefringence. Also in OSMF with OSCC, 6 cases showing predominantly parallel collagen fibers in relation with the epithelium. 7 cases was showing haphazardly arrenged collagen fibers and 2 cases were showing combination of both (Table 2).

In this study we found that, there is gradual change in birefringence of collagen fibers from red to orange red- yellowish orange to yellowish green as from OSMF to OSMF with OSCC and to OSCC.

V. Discussion

As stated in the letterature, elements which plays important role in tumour progression are stromal elements which surrounds the tumour, that includes endothelial cell, fibroblasts and inflammatory cell as a know fact collagen is triple helical structure and its molecules are affluent in basic amino acid, therefore, having strong affinity for acidic dyes giving strong reaction with the acidic dyes. Picrosirius red is acidic dye that is having six sulfonic group, so used to stain collagen in tissue sections.

The orange red- red colour of collagen which was observed in cases of OSMF was because of tight packing of collagen fibers suggestive of presence of thick fibers in the extracellular matrix. As the collagen in OSMF grade III cases were tightly packed bundles, so it difficult to identify individual collagen fibers, this is due to increased in thickness of collagen fibers as the disease advanced.

The colour red is owing to firm wrapping of collagen fibers that’s why there is decreased intensity of birefringence and alteration in polarization colour due to which changes in extracellular matrix, imbalance between production and degradation. The gradual change from yellowish orange to greenish yellow was more significant when OSMF is transforming to OSCC. The haphazardly arrangement of collagen fibers was indicative of increased collagenolytic enzyme activity which were observed during transformation of preneoplastic to carcinoma stage. Also when premalignant state is transformed to carcinoma there is increase in collagenolytic enzyme activity. Tumor cell produces collagenases which has ability to degrade Type-I collagen and helps in invasion and metastasis.

Many authors suggested that the subunits of collagen become thinner to form a fibers. Also many of them suggested that the periodicity of collagen interlinking is not changed and the collagen form is the normal. There are two origin of collagen fibers to be suggested, one is tumor cell origin which helps the tumor cell to progress reducing in the thickness. Another is the stromal origin which prevent tumor spread further. The origin of these fibers was considered to be the tumor cell fibroblast and the collagen by these cells is thought to be procollagen which is a pathologic collagen.

In the present study, the cause of increased deposition of collagen in the connective tissue stroma is due to decreased in collagenase activity. The reason for this was, beetal quide which is the primary cause of OSMF content areca nut, flavinoids, alkaloids which stimulates the fibroblast, causing increased deposition of collagen and also leads to stabilization of collagen structure. Lots of work were done on collagen by various method we preferred picrosirius red stain as it has capacity to demonstrate thin collagen with the help of polarized microscopy. As there was formation of dye and collagen parallel relationship which helps to enhance birefringence.

The results of this study are consistence with other studies which illustrated the parallel orientation of collagen fibers with respect to epithelium and colour changes observed in OSMF, OSCC with OSMF and in OSCC. The disparity in colour pattern of collagen fibers might exist due to asorted growth factors and cytokines causing fibroblast proliferation and extracellular matrix results in the arrangement of immature collagen.

Since the collagen is converted from mature to become immature, the modification in proteoglycan content of fiber would be reason of dehydration of fibers thereby decreasing the diameter of collagen fibers.

Type I collagen fiber showed a strong birefringence of red, orange and yellow colour and a weak birefringence when the fiber were type III collagen so called thin fiber by polarized microscopy.

According to Junqueira etal and Montes etal, the colour change can be attributed to carcinogenic action of...
MMPs. Pathological breakdown of matrix by tumor cells, promote tumor progression. In the present study, colour changes seen are clear indicator of stromal tissue alteration which can be related to carcinogenic events taking place during tumorogenesis.

Breast cancer studies showed that increase in collagen in extracellular matrix increases the mechanical stiffness and imparts resistance to the tumor. Nuclear resonance studies by Sharf et al shows a colour orange corresponds with tight packing and greenish yellow to poorly packed fibers.

This study further supported by, in follicular thyroid carcinoma higher frequency of yellow green collagen fibers at the site of invasion and orange red collagen fibers in noninvasive sites. Hence, there is a correlation of change in polarization color of collagen fibers with the changes in the connective tissue stroma, which indicate connective tissue changes could also be indicative of neoplastic transformation.

VI. Conclusion

Hence, the change in polarization colors from OSMF to OSCC is a radical change in the collagen orientation as well as thickness which could be indicative of numerous enzymatic actions, which are taking place as a part of change in connective tissue which occurred during malignant transformation. The observations of the present study indicated that the change in orientation and thickness of collagen fibers in OSMF could acts as a prognostic marker indicative of malignant transformation.
