Comparative Study of Recent Management of Peptic Ulcer Perforation

Dr. Nitin Parashar, Dr. Atul Krishna, Dr. Vijay Agarwal, Dr. Dhanesh Kumar, Dr. M.K. Maheswari

Abstract: Peptic ulcers include gastric ulcers, Esophageal ulcers and Duodenal ulcers. The aim of this study is to have a clinical presentation of peptic ulcer perforation and to study the various method and management of peptic ulcer perforation. The treatment of perforated ulcer disease continues to evolve because of recent advances in pharmacology, bacteriology, and operative technique. The main surgical treatment option was simple closure with Graham patch.

I. Introduction

Peptic ulcer is a term used to describe lesions that can be found in the upper gastrointestinal tract (Esophagus, Stomach and Duodenum) and more rarely in jejunum and in a Meckel’s diverticulum. It consists of ulcers that go deeper than the “muscularis mucosa” layer. The term “peptic” is derived from the fact that for centuries it was believed that the sole cause of peptic ulcers was due to excessive production of gastric juice, the surplus hydrochloric acid and pepsin being considered only culprits of the ulcers. There was even the motto “no acid, no ulcer” coined by Schwartz, one of the most respected medical authorities at that time. After this initial motto of “no acid, no ulcer”, several interplaying factors were found to be responsible for peptic ulcer. The multifactorial complexity of the disease was considered to be the result of imbalance between aggressive and defensive factors. Aggressive factors are Hydrochloric acid, pepsin, digestive enzymes, ethanol, caffeine from coffee, methyl xanthines from chocolate, smoking, paper, spices, bile acids, stress, medications that are damaging to the upper gastrointestinal tract. Defensive factors include mucobicarbonate layer, prostaglandins products, cellular renovation and blood flow. Then the Helicobacter pylori was discovered by chance. The Australian researchers Warren and Marshall made this historical finding in 1982. Surprisingly when they returned after a long holiday, to their laboratory, the already sown gastric fragments from peptic ulcer were positive for bacterium colonies. This explained the imbalance between aggressive and defensive factors, that caused most of the peptic ulcer cases. Now the peptic ulcer turned out to be a misnomer once we consider the importance of H. pylori, and nowadays there is a proposition to change it to Infecto-pptic ulcer.

II. Methods

This prospective study of 2 years in which a total 96 patients were recruited. We had managed 30 had laparoscopic surgical method and all rest 66 patients with open surgery method. The main surgical treatment option was simple closure with Graham patch.

Follow up after discharge from the hospital 14 days, 28 days, 1 & 1/2 month, 3 months and 6 months. The data was analyzed in statistical program SPSS version 20.0. Fisher’s exact test of Chi-squared was applied for categorical variables to calculate frequencies and percentages among the groups.

III. Results

96 patients underwent surgical repair of perforated peptic ulcer disease (30 laparoscopic repairs and 66 open repairs; the common number of patients being in the 30 to 50 year age group. There was no difference in age and the time to surgery in both groups. The mean operating time of the laparoscopic patch repair was significantly longer than the open procedure (56.11: 61.13 minutes; p = 0.001). In addition there was a significant decrease in the time that the nasogastric tube (mean: 6 days laparoscopic versus 8 days open), urinary catheter (mean: 7 days laparoscopic versus 9 days open) and abdominal drain (mean: 6 days laparoscopic versus 8 days open) were required during the postoperative period. Patients who had undergone laparoscopic repair returned to normal diet (mean: 7 days laparoscopic versus 9 days open). In addition, patients who had undergone laparoscopic repair required a shorter in-patient hospital stay (mean: 7 days laparoscopic versus 9 days open).

IV. Discussion

V. Laparoscopic repair is a viable and safe surgical option for patients with perforated peptic ulcer disease and should be considered for all patients, providing that the necessary expertise is available. We found that younger age groups (31-50 years) are frequently affected due to the prevailing young age structure of the U.P. population.

VI. Laparoscopic repair of perforated peptic ulcer is a safe and reliable procedure and is proven to be efficient. Even though it was associated with longer operating time, it had no impact on outcome.

VII. It had less postoperative pain, reduced chest complications and reduced analgesic usage, shorter postoperative hospital stay, and earlier return to normal daily activities than the conventional open repair.

VIII. It has lesser morbidity and mortality as compared to open group. Data from the present study indicate that laparoscopic surgical treatment of patients with peptic ulcer perforation can be implemented and completed safely in a large proportion of patients with this life-threatening condition, given that the responsible surgical team has the appropriate technical expertise.

IX. Upper GI endoscopy is the method of choice for investigation of uncomplicated ulcers as well as bleeding peptic ulcers, while plain X-ray abdomen is still the preferred investigation in suspected cases of perforation.

X. We need to do study with more number of cases as to claim advantage of laparoscopic surgery.

XI. Conclusion

Based on our study, we conclude that the laparoscopic repair of perforated peptic ulcer is safe and reliable procedure, it has lesser morbidity and mortality compare to open surgery, given that responsible surgical team has appropriate technical expertise.
