Alternative Sampling Strategy Based upon Coefficient of Mean Deviation When Auxiliary Information is Available

Spersh Bhatt
Department of Statistics, DSB Campus, Nainital, Uttarakhand, India

Abstract: It is well known that in order to improve the efficiencies of the estimates probability sampling is preferred over non probability sampling. If the difference in the size of the units is large enough to affect the study, we make use of PPS sampling where the probability of selecting a unit is proportional to the size measure of the unit. Sometimes we may be confronted with situations where information on a character closely related to the main variable is available from a previous study or other secondary sources. Various authors have utilized this auxiliary information by taking the initial probability of selection equal to the size measure of the auxiliary information. This scheme however fails to give best results when the population under consideration is skewed. The paper presents an alternative without replacement sampling strategy obtained by utilizing auxiliary information to modify the initial probability of selection of the units. A computer program was developed in Visual Basic to find out the probabilities of selection and the variance of the sampling strategy proposed using the Horvitz Thompson estimator of population total. The empirical comparison of the proposed strategy with the existing Midzuno-Sen strategy shows that the proposed scheme performs better than the Midzuno-Sen strategy when the population is skewed.

Keywords and Phrases: coefficient of mean deviation, probability of selection, relative efficiency, sampling strategy, sampling design

I. Introduction

It is well known that to avoid personal bias, random sampling is preferred over non random sampling. Attaching equal probability of selection to different units yields the method of simple random sampling. When unequal probabilities of selection are attached to different units in the population, it is called unequal probability sampling. If a sample from a finite population is drawn, usually the values of some character 'x' closely related to the main character of interest is available for all units of the population. The variable 'x' which is suitably normed, is often taken as a measure of the size of the unit. This occurs in socio-economic, agricultural and industrial surveys which are accompanied with the knowledge of past data. A unit with higher values of 'x' shall contribute more to the population total of main variable, than those with smaller sizes. One expects that, a selection procedure which gives higher selection probabilities to bigger units than to smaller units, should be more efficient than simple random sampling.

Consider a finite population 'U' of distinguishable units labeled 1,2,3,........,N. The collection of all possible samples is called the sample space denoted by 'S'. With each sample 's' a probability p(s) is attached which is the probability of drawing the sample 's'.

We thus have

\[
\begin{align*}
(1) & \quad p(s) \geq 0 \\
(2) & \quad \sum_{s \in S} p(s) = 1
\end{align*}
\]

Here the sample from 'U' is an ordered sequence of labels from 'U' and represented by

\[
S = (i_1, i_2, \ldots, i_n)
\]

where \(i_k\) is the label of the unit drawn at the \(k^{th}\) draw and \(1 \leq k \leq n\). The labels represent the units drawn with or without replacement in 'n' consecutive draws, hence the labels need not be distinct from each other. The size of the sample is 'n' and 'r' is the effective sample size (which is the number of distinct labels in 'S').

Let \(P_i\) denote the probability that the \(i^{th}\) unit is selected in the sample from the population. By the addition law of probability

\[
P_i = \sum_{s \in S} p(s)
\]

where summation is taken over all possible samples containing the \(i^{th}\) unit of the population. It is further assumed that \(p(s)\) is such that \(P_i > 0\) for \(i = 1, 2, \ldots, N\).
The collection $S = \{s\}$ with a probability measure $P = \{p(s)\}$, defined on 'S', such that $p(s) \geq 0$ and $\sum_{s \in S} p(s) = 1$ is called the sampling design and is denoted by $D(S,P)$. A sampling procedure in which $p_i$ (the probability of including the unit $i$ in a sample of size $n$) is $np_i$. These are referred to as $\pi$-ps methods. Here $p_i$ is the probability of selecting the $i^{th}$ unit of the population into the sample at the first draw. To estimate the population mean or total with such procedures, the commonly used estimator is the Horvitz-Thompson (H-T) estimator.

The unbiased H-T estimator for population total $Y$ can also be written as

$$\hat{Y}_{HT} = \sum_{i=1}^{N} \frac{Y_i \delta_i}{P_i}$$

where $\delta_i = \begin{cases} 1, & \text{if } i \in S \\ 0, & \text{otherwise} \end{cases}$

The variance of the H-T estimator for population total $Y$ is given by

$$V(\hat{Y}_{HT}) = \sum_{i=1}^{N} \frac{1 - P_i}{P_j} Y_i^2 + 2 \sum_{i,j}^{N} \left( \frac{P_{ij} - P_i P_j}{P_i P_j} \right) Y_i Y_j$$

where $i,j = 1, 2, 3, ..., N$.

Here $P_{ij}$ is the probability of including the units $i$ and $j$ in the sample and $P_j = \sum_{i,j} p(s)$

Yates and Grundy (1953) provided an alternative estimator of the population total $Y$, which is given by

$$V(\hat{Y}_{HT})_{YG} = \sum_{i,j}^{N} \left( P_i P_j - P_{ij} \left( \frac{Y_i}{P_i} - \frac{Y_j}{P_j} \right)^2 \right)$$

Some estimators of variance of the Horvitz-Thompson estimator have been given by Yates and Grundy and Sen (1953), Jessen (1969) and Ramakrishnan (1971).

Midzuno (1952) developed a sampling strategy in which the unit at the first draw is selected with unequal probability of selection. At all subsequent draws they are selected with equal probability and without replacement.

In the Midzuno-Sen scheme of probability proportional to size (pps) sampling the probability that the $i^{th}$ unit is included in the sample is given by

$$\left( \frac{N-n}{N-1} \right) P_i + \left( \frac{n-1}{N-1} \right)$$

and the probability that both $i^{th}$ and $j^{th}$ units are included in the sample is given by

$$\frac{n-1}{N-1} \left( \frac{N-n}{N-2} \left( P_i + P_j \right) + \frac{n-2}{N-2} \right)$$

In the above scheme the probability of selection for a specific size ‘s’ is given by

$$\sum_{i \in s} X_i$$

$$\sum_{s \in S} \sum_{i \in s} X_i$$

Midzuno's scheme made $\pi$-ps has been considered by Rao (1963), Sankaranarayanan (1969), Chaudhuri (1974), Mukhopadhyay (1974) among others.

The Midzuno scheme though easy to implement is known to be less efficient in comparison to other unequal probability schemes. On the other hand Sampford scheme is known to be usually a good performer in the class of unequal probability schemes. This scheme however suffers from the drawback that it is rather difficult to implement particularly when $n > 2$.

Section 2 of the paper presents the methodology of obtaining the proposed strategy and the empirical study used for comparing the proposed strategy with the conventional Midzuno-Sen scheme.

Section 3 of the paper gives the tables and graphs giving the variance comparison of the Horvitz Thompson estimator under the proposed scheme and the Midzuno scheme.
II. Methodology and Empirical Study

Mean deviation for a sample of size 's', for auxiliary information is given by

\[ M.D. = \frac{1}{n} \sum_{i \in S} |X_i - A| \]

where 'A' is any measure of central tendency. It is now proposed that the average for the chapter on hand, for a sample of size 's', is the mean given by

\[ \bar{X}_s = \frac{1}{n} \sum_{i \in S} X_i \]

The coefficient of mean deviation (about the mean), say CMD, is thus given as:

\[ CMD = \frac{\sum_{i \in S} |X_i - \bar{X}_s|}{\bar{X}_s} \]

It is now proposed that the probability of selection of a sample be given as

\[ p(s) = \frac{CMD}{\sum_{s \in S} CMD} \quad \text{…………(α)} \]

It can be easily shown that the Horvitz-Thompson estimator under the above scheme is unbiased for the population total.

The empirical comparison for variance under the Midzuno scheme and the proposed one based on Coefficient of Mean Deviation has been done using a computer program developed in Visual Basic.

\[ p_i \text{ and } p_{ij} \text{ have been calculated on the basis of (α) and then the following Yates –Grundy formula for variance is used} \]

\[ V(\hat{Y}_{HT})_{YG} = \sum_{i,j} \left( p_i p_j - p_{ij} \right) \left( \frac{Y_i - Y_j}{P_i P_j} \right)^2 \]

III. Tables for Efficiency Comparisons

To compare the two schemes 10 natural populations have been considered. These have been taken from Murthy (1977). Here Y stands for the number of cultivators in 1961 and X for area in 1951. Five cases have been considered for N=7 and n=3, two cases for N=8 and n=3 and three cases for N=9 and n=3. The first natural population for N=7 and n=3 along with the \( p_i \) and \( p_{ij} \) values have been given below.

Natural Populations for N=7, n=3

<table>

IV. Conclusion

From the efficiency comparisons given in the tables 1, 2 and 3 above it can be concluded that the proposed strategy performs better than the existing strategy, specially in cases when the population is skewed.
