**ABSTRACT:-** Web application is an application that is accessed over a network such as the Internet. They are increasingly used for critical services, in order to adopt with increase in demand and data complexity web application are moved to multitier Design. As web servers must be publicly available around the clock the server is an easy target for outside intruders. Thus web applications are become a popular and valuable target for security attacks. These attacks have recently become more diverse and attention of an attacker have been shifted from attacking the front-end and exploiting vulnerabilities of the web applications in order to corrupt the back-end database system. In order to penetrate their targets, attackers may exploit well known service vulnerabilities. To protect multitier web applications several intrusion detection systems has been proposed. An Intrusion Detection System (IDS) is used to detect potential violations in database security. In every database, some of the attributes are considered more sensitive to malicious modifications compared to others.

Keywords:- Light weight virtualization, Anomaly Intrusion detection, Container

I.

## INTRODUCTION

Intrusion detection plays one of the key roles in computer system security techniques.

An intrusion detection system (IDS) is a device or software application that monitors network or system activities for malicious activities or policy violations and produces alerts. There are two general approaches to intrusion detection: anomaly detection and misuse detection. A signature based IDS works similar to anti-virus software. It employs a signature database of well-known attacks, and a successful match with current input raises an alert. Similarly to anti-virus software, which fails to identify unknown viruses a signature-based IDS fails to detect unknown attacks. An Anomaly-Based Intrusion Detection [1] system is a system for detecting computer intrusions and misuse by monitoring system activity and classifying it as either normal or anomalous. Double guard detection [2] achieved by a lightweight virtualization technique [8] to assign each user's web session to a dedicated container, which is an isolated virtual computing environment. We use the container ID to accurately associate the web request with the subsequent DB queries. Thus, DoubleGuard can build a causal mapping profile by taking both the web server and DB traffic into account. Full virtualization and paravirtualization are not the only approaches being taken, However an alternative is lightweight virtualization, generally based on some sort of container concept. With containers, a group of processes still appears to have its own dedicated system, but it is really running in a specially isolated environment. All the containers run on top of the same kernel with containers, the ability to run different operating systems is it lost, as is the strong separation between virtual systems. Double guard will not want to give root access to processes running within a container environment. On the other hand, containers can have considerable performance advantages, enabling large numbers of them to run on the same physical host.

#### II. RELATED WORK

A network intrusion detection system can be classified into two types: signature detection and anomaly detection. Anomaly detection [1] [2] first requires the IDS to define the characteristics of correct and acceptable static from dynamic behavior of the system. It is used to detect the abnormal behavior of the system. We first define the normal behavior of the system and create profile of the user. In early IDS system that use the independent IDS used. Double guard [2] use dependent IDS used. Double guard use the container ID using this ID each user session is assigned to each id. Our approach does not require input validation, source code validation and know the application logic. Double guard uses the light weight virtualization to create and destroy. We identify the causal relationship between web server request and database request.

#### III. SYSTEM ARCHITECTURE

We initially set up our threat model to include our assumptions and the types of attacks we are aiming to protect against. We assume that both the web and the database servers are vulnerable. Attacks are network borne and come from the web clients; they can launch application layer attacks to compromise the web servers they are connecting.

#### **Fig 1. Three-Tier Architecture**

The above architecture illustrates the classic three-tier model. At the database side, we are unable to tell which transaction corresponds to which client request. The communication between the web server and the database server is not separated, and we can hardly understand the relationships among them. According to above architecture, if Client 2 is malicious and takes over the web server, all subsequent database transactions become suspect, as well as the response to the client.

#### IV. ENHANCING THE NORMALITY MODEL

This container-based and session-separated web server architecture not only enhances the security performances but also provides us with the isolated information flows that are separated in each container session. It allows us to identify the mapping between the web server requests and the subsequent DB queries, and to utilize such a mapping model to detect abnormal behaviors on a session/client level. In typical three-tiered web server architecture, the web server receives HTTP requests from user clients and then issues SQL queries to the database server to retrieve and update data. These SQL queries are causally dependent on the web request hitting the web server. We want to model such causal mapping relationships of all legitimate.

The above model depicts how communications are categorized as sessions and how database transactions can be related to a corresponding session. In the above diagram, Client 2 will only compromise the VE 2, and the corresponding database transaction set T2 will be the only affected section of data within the database.

It is impossible for a database server to determine which SQL queries are the results of which web requests, much less to find out the relationship between them. Even if we knew the application logic of the web server and were to build a correct model, it would be impossible to use such a model to detect attacks within huge amounts of concurrent real traffic unless we had a mechanism to identify the pair of the HTTP request and SQL queries that are causally generated by the HTTP request. However, within our container-based web servers, it is a straight forward matter to identify the causal pairs of web requests and resulting SQL queries in a

National Conference on Emerging Trends and Innovations in Engineering & Technology 21 | Page Dhaanish Ahmed College of Engineering

given session. Moreover, as traffic can easily be separated by session, it becomes possible for us to compare and analyze the request and queries across different sessions.

Fig 2. Dual security model

To that end, we put sensors at both sides of the servers. At the web server, our sensors are deployed on the host system and cannot be attacked directly since only the virtualized containers are exposed to attackers. Our sensors will not be attacked at the database server either, as we assume that the attacker cannot completely take control of the database server. In fact, we assume that our sensors cannot be attacked and can always capture correct traffic information at both ends. Fig. b shows the locations of our sensors.

Once we build the mapping model, it can be used to detect abnormal behaviors. Both the web request and the database queries within each session should be in accordance with the model. If there exists any request or query that violates the normality model within a session, then the session will be treated as a possible attack.

## V. MODELING DETERMINISTIC MAPPING AND PATTERNS

Due to their diverse functionality, different web applications exhibit different characteristics. Many websites serve only static content, which is updated and often managed by a Content Management System (CMS). For a static website, we can build an accurate model of the mapping relationships between web requests and database queries since the links are static and clicking on the same link always returns the same information.

#### **5.1 Inferring Mapping Relations**

Mapping relation explain about how the request and corresponding query are matched, causal relationship between rm to {qn,qp}. Here qn,qp are mention the different database query. The possible mapping patterns as follows.

#### **5.2 Deterministic Mapping**

This is the most common and perfectly matched pattern. That is to say that web request rm appears in all traffic with the SQL queries set Qn. The mapping pattern is then rm to Qn. In static websites, this type of mapping comprises the majority of cases since the same results should be returned for each time a user visits the same link.

#### 5.3 Empty Query Set

In special cases, the SQL query set may be the empty set. This implies that the web request neither causes nor generates any database queries.

#### 5.4 No Matched Request

In some cases, the web server may periodically submit queries to the database server in order to conduct some scheduled tasks, such as cron jobs for archiving or backup. This is not driven by any web request, similar to the reverse case of the Empty Query Set mapping pattern. These queries cannot match up with any web requests, and we keep these unmatched queries in a set NMR. During the testing phase, any query within set NMR is considered legitimate. The size of NMR depends on web server logic, but it is typically small.

#### 5.5 Non Deterministic Mapping

The same web request may result in different SQL query sets based on input parameters or the status of the webpage at the time the web request is received. In fact, these different SQL query sets do not appear randomly, and there exists a candidate pool of query sets (e.g.,  $\{Qn;Qp;Qq\ldots\}$ ). Each time that the same type of web request arrives, it always matches up with one (and only one) of the query sets in the pool. The mapping pattern is

Therefore, it is difficult to identify traffic that matches this pattern. This happens only within dynamic websites, such as blogs or forum sites.

## VARIOUS TYPES OF ATTACK

Once the model is built, it can be used to detect malicious Sessions. Double Guard detects the following types of attack.

# User (Attacker) Admin Request Admin Request Admin Request Admin Queries ATTACK Admin Database Server Server

## 6.1 Privilege Escalation Attack

VI.

#### Fig 3. Privilege Escalation Attack

Let's assume that the website serves both regular users and administrators. For a regular user, the web request  $r_u$  will trigger the set of SQL queries  $Q_u$ ; for an administrator, the request  $r_a$  will trigger the set of admin level queries  $Q_a$ . Now suppose that an attacker logs into the web server as a normal user, upgrades his/her privileges, and triggers admin queries so as to obtain an administrator's data. This attack can never be detected by either the web server IDS or the database IDS since both  $r_u$  and  $Q_a$  are legitimate requests and queries. Our approach, however, can detect this type of attack since the DB query  $Q_a$  does not match the request  $r_u$ , according to our mapping model.

## 6.2 Hijack Future Session Attack

This class of attack is mainly based on web server side. An attacker takes over web server by hijack the other user sessions by sending spoofed replies. In double guard it is detected by causal mapping a request without query it is not accepted. Fortunately, the isolation property of our container based web server architecture can also prevent this type of attack. As each user's web requests are isolated into a separate container, an attacker can never break into other users' sessions.

Fig 4. Hijack Future Session Attack

#### **6.3 Injection Attack**

Fig 5. Injection Attack

Attacks such as SQL injection do not require compromising the web server. Attackers can use existing vulnerabilities in the web server logic to inject the data or string content that contains the exploits and then use the web server to relay these exploits to attack the back-end database. Since our approach provides a two-tier detection, even if the exploits are accepted by the web server, the relayed contents to the DB server would not be able to take on the expected structure for the given web server request. For instance, since the SQL injection attack changes the structure of the SQL queries, even if the injected data were to go through the web server side, it would generate SQL queries in a different structure that could be detected as a deviation from the SQL query structure that would normally follow such a web request.

National Conference on Emerging Trends and Innovations in Engineering & Technology 24 | Page Dhaanish Ahmed College of Engineering

#### 6.4 Direct DB Attack

It is possible for an attacker to bypass the web server or firewalls and connect directly to the database. An attacker could also have already taken over the web server and be submitting such queries from the web server without sending web requests. Without matched web requests for such queries, a web server IDS could detect neither. Furthermore, if these DB queries were within the set of allowed queries, then the database IDS it would not detect it either. However, this type of attack can be caught with our approach since we cannot match any web requests with these queries.

## Fig 6. Direct DB Attack

#### VII. CONCLUSION

In this way we surveyed few techniques which are meant for intrusion detection against multitier web applications. Some of the technique use single IDS to detect and prevent web server from malicious request while some approach use combined approach to detect intrusions at both web and database level. Apart from all above discussed approach the last approach is having some additional detection capability to detect attack where normal traffic is used as means to launch database attack. Because of container based and session separated approach of Double guard use multiple input streams to produce alerts. Such correlation of different data streams provides a better characterization of the system for Anomaly detection because the intrusion sensor has a more Precise normality model that detects a wider range of threats. This approach is more advantageous in sense that monitoring both web and subsequent database requests, we are able to detect attacks that an independent IDS would not be able to identify.
